Abstract—This study quantified selection by analyzing the survival rate of the participants and nonparticipants in a 4-year prospective, multicenter cohort study. In addition, the differences between these groups were analyzed. Surgeons of six hospitals in the northern Netherlands referred, in total, 225 patients to the study. Of these patients, 60% (n = 134) participated in the prospective study by filling in questionnaires; the others (nonparticipants) were followed over time through their records. No significant differences were found in sex and level of amputation between participants and nonparticipants; however, of the two groups, nonparticipants were significantly older. Reason for amputation was peripheral vascular disease (PVD) for 67% (n = 90) of the participants and 82% (n = 75) of the nonparticipants. The mean survival time of the participants and nonparticipants was 36.1 and 29.6 months, respectively. Within PVD, the mean survival time of participants and nonparticipants was 34.4 and 27.6 months, respectively. To summarize, our article gives an overview of the survival rates in a prospective study on patients scheduled for a limb amputation. Our study sample was biased by selection and death. Participants were generally healthier than nonparticipants.

INTRODUCTION

From historical cohort studies the patient survival rate after a lower-limb amputation because of vascular problems is clearly moderate to low over time [1–12]. However, prospective studies on lower-limb amputees seldom report their survival rates, inclusion and exclusion criteria, and/or referral and dropout rates (death included) [13–20]. Thus, in these studies, little is known about bias through selective referral, number of dropouts, or mortality. The same is true for studies concerning predictors of functional outcome or quality of life after a lower-limb amputation [21–27].

In amputation research, selection bias in study samples has probably occurred but has seldom been quantified. A consequence of this selection is that amputees who managed to reach the prosthetic stage of the rehabilitation process were a small subset of those who have had an amputation. However, in research, one wants to

generalize the results of the study to the target population. To be able to do so, researchers must use a random sample from the target population, which should have the same properties as the research population from which the research sample is drawn.

In 2003, a 4-year prospective multicenter cohort study on limb amputees was initiated at the University Medical Center Groningen (UMCG), Groningen, the Netherlands. During that prospective study, apparently, selection also occurred and a substantial number of patients referred did not fulfill inclusion criteria and, consequently, became nonparticipants. In the current study, we aimed to quantify selection by analyzing the survival rate of the participants and nonparticipants studied. In addition, the differences between these groups were analyzed.

METHODS

Patients

Patients scheduled for limb amputation were recruited for a prospective study in the northern Netherlands from November 2003 to May 2007. The survival data presented here were part of this prospective multicenter cohort study on phantom pain, phantom sensations, and residual-limb pain after a limb amputation. To ensure sufficient inflow of patients, vascular surgeons in 12 of the 13 hospitals in the northern Netherlands and surgeons of UMCG’s oncological, orthopedic, and hand surgery and traumatology departments were asked to participate. Surgeons were invited to a meeting in which they were informed about the aims and logistics of the study. After the meeting, the surgeons received a written copy of the agreements made during the meeting. In addition, they were sent the inclusion and exclusion criteria, procedures for referring patients to the primary investigator, and the period they could refer potential candidates (November 2003–May 2007). Surgeons also agreed that if they decided to exclude a patient, they would send the researcher the patient’s characteristics and surgical information.

During the study, we sent eight newsletters containing both the current state of affairs and a reminder to refer patients to all surgeons. In addition, we regularly telephoned the hospital wards in question. About halfway through the study, we presented information to the surgeons about the number of patients included and excluded by hospital.

Inclusion criteria for the prospective study were (1) a minimum age of 18 years, (2) an amputation level through the metacarpophalangeal or metatarsophalangeal joints or more proximal, (3) a first amputation of the limb, (4) the ability to fill in the first questionnaire before the amputation or not more than 5 days after the amputation, and (5) a sufficient command of spoken and written Dutch to fill in questionnaires. Patients were excluded if they were too ill to fill in the questionnaires or showed signs of clinical dementia to such an extent that they could not be expected to fill in the questionnaires (comorbidity).

Data Entry

We recorded patients’ characteristics and the reason for, the level of, and date of amputation. Lower-limb amputations were categorized as distal (transfibial, ankle, or foot), knee disarticulation, or proximal (pelvis, hip, or transfemoral). Upper-limb amputations were categorized as distal (transradial or wrist) or proximal (forequarter, shoulder, or transhumeral); no elbow disarticulations had been performed. If patients underwent a second amputation of the same limb during the study period, we used the date of the first amputation for statistical analyses. If a patient died during the follow-up, we noted the date of death. On 1 November 2007, we investigated the survival rate of all patients referred by analyzing their records kept by participating hospitals or by consulting the patients’ general practitioners.

Participants were patients who filled in questionnaires over time, and nonparticipants were followed over time through their records. Detailed outcomes of the prospective study have been reported elsewhere [28].

Statistics

We analyzed descriptive statistics using SPSS version 16.0 (Chicago, Illinois) for Windows. Differences between the participants and nonparticipants were analyzed with t-tests for independent samples and χ²-tests, as appropriate. Kaplan-Meier survival curves were drawn for the participants and nonparticipants and log-rank tests were completed. Values of p ≤ 0.05 were considered statistically significant. Data are presented in tables, enabling detailed comparison with literature data, and in figures, providing an overview of events over time.
RESULTS

Patients were referred from one university hospital and five general hospitals in the northern Netherlands. In total, the data of 225 patients referred were available. Of these patients, 134 (participants) were followed longitudinally by means of questionnaires during a maximum of 4 years and 91 (nonparticipants) were only followed over time through their records (16 patients refused to participate and 75 patients did not meet the inclusion criteria). Of those not meeting the inclusion criteria, 46 patients were too ill or had signs of a clinical dementia, 7 had a previous ipsilateral amputation, 19 exceeded the time interval by 5 days between amputation and the first questionnaire, 1 was younger than 18 years, and 2 patients did not speak or read Dutch (Figure 1).

The patients’ characteristics and the reason for and level of amputation are summarized in Table 1. No significant differences were found in sex ($p = 0.50$) and level of amputation ($p = 0.50$) between participants and nonparticipants. Nonparticipants were significantly older than participants ($p = 0.04$). More nonparticipants (82%) than participants (67%) had an amputation because of peripheral vascular disease (PVD), whereas more participants had an amputation because of trauma or complex regional pain syndrome type I (CRPS I) or cancer ($p = 0.03$) (Table 1). Within the group of patients who had an amputation because of PVD, the mean survival time of participants (34.4 months) was generally longer than that of nonparticipants (27.6 months) ($p = 0.05$).

All patients’ mean survival time after a proximal amputation was 30.0 months, after a knee disarticulation 36.5 months, and after a distal amputation 34.9 months ($p = 0.25$) (Figure 4). Detailed 4-year survival data of all amputees, categorized according to sex and reason for and level of amputation, are presented in Table 2.

Within the group of amputees, 6 percent ($n = 14$) had had an upper-limb amputation that was proximal in 71 percent ($n = 10$) of the patients. The main reason for upper-limb amputation was a trauma or CRPS I ($71\%, n = 10$). One of the participants with an upper-limb amputation died from cancer 6.5 months after his amputation.

DISCUSSION

The results of the current study confirm a moderate survival rate of patients after a limb amputation. Overall, a larger percentage of the participants survived than nonparticipants.

As we have already stated, in research, one wants to generalize the study results to the target population. To be able to do so, researchers must use a random sample from the target population. Looking at the survival rates of the participants and nonparticipants found in the current study, we noted a clear bias in population: a healthier and somewhat younger population with less vascular amputations participated.

When the survival rates of the current study were compared with those of other prospective studies on amputation and phantom pain, we found that the prospective studies only reported survival of included patients, as a rule. The reported survival rate ranges from 59 to
percent 6 months after amputation [13–15,17–20] and from 59 to 67 percent 12 months after amputation [15–16,18–20]. Only one study provided a 2-year follow-up [14]: the survival rate was 59 percent. The numbers of amputees who participated in these prospective studies were relatively small (n = 21 to n = 60). The studies mainly included patients who had an amputation because of PVD—a group of amputees having a large chance of dying relatively soon after the amputation. Furthermore, the studies seldom provided the number of patients referred to the study, the number of patients excluded and the reasons for exclusion, and the dropout rate by death [13–17,20]. Consequently, the type of selection bias that

Note: Reasons for amputation were either PVD with and without diabetes mellitus, ulcer, infection (PVD), cancer, or trauma or CRPS I. Levels of amputation of lower limb were either proximal (pelvis, hip, or transfemoral) or knee disarticulation or distal (transtibial, ankle, or foot). Levels of amputation of upper limb were either proximal (forequarter, shoulder, or transhumeral) or distal (transradial or wrist). CRPS I = complex regional pain syndrome type I, PVD = peripheral vascular disease, SD = standard deviation.
occurred is unclear. If the same bias occurred in those studies as in our study, they probably investigated a healthier and younger subset of amputees [13–17]. Only Nikolajsen et al. reported the number of patients scheduled for an amputation \( (n = 157) \), patients excluded \( (97/157) \) and reasons for exclusion, and dropouts (death included) \[18–19\]. They also reported that participants were healthier than nonparticipants. Other authors reported the number of dropouts \[17,20\], the reason for excluding patients \[13–17\], or the number of patients excluded \[17\]. Consequently, survival data from our current study cannot be adequately compared with data of those studies. However, from the data in studies by Nikolajsen et al. \[18–19\], one can deduce that at least 44 percent of the excluded patients were in poorer general health than included patients. Other studies have not clearly reported how many patients were excluded for reasons of poor general health.

Concerning predictors of functional outcome after a limb amputation, excluding severely disabled patients, a prospective study found a survival rate of 85 percent within the first year \[23\]. Primarily, patients who went to a nursing home died, probably because of poor general health. Perhaps this study’s survival rate was high compared with that of other prospective studies because of its exclusion criteria (patients not understanding the test instructions and being severely disabled without any walking ability before the amputation for reasons not related to PVD) \[23\]. In cross-sectional studies concerning functional outcome after a limb amputation, survival rates were not a concern because only survivors could be selected \[21–22,24–27,29\]. Additionally, explicit inclusion or exclusion criteria for those studies were seldom specified, except that the patients had to have undergone a lower-limb amputation and referred for a limb fitting (these patients formed a kind of convenience sample).

In historical cohort studies, an estimation of the survival rates after amputation is obtained from historical data, usually from different sources (general databases, hospital records, and medical insurance and Central Person Register databases). The total number of patients amputated is known, and the number of deaths is recorded as usual.

In certain historical cohort studies, the 1-year survival rates ranged from 49 to 73 percent \[1–2,4,8,10,12,30\] and the longer term (interval 5-year) survival rates were 26 percent \[1–2,12\]. The number of patient records in these historical cohort studies was large \( (n = 174 \text{ to } n = 21,520) \) \[1–2,4,6,8–11,30\].

The limitation of the current study is that the number of referred patients scheduled for a lower-limb amputation was considerably smaller than expected. On the basis of earlier Dutch amputation studies \[3,21\], the population of the northern Netherlands (comprising the provinces of
Groningen, Friesland, and Drenthe) [31], and the number of participating hospitals, an estimated 150 to 170 new patients with a lower-limb amputation could be referred to the current study each year. Despite all efforts, only 35 to 40 percent (n = 211, inclusion period 3 1/2 years) of the estimated population of lower-limb amputees in the northern Netherlands were referred, indicating a considerable selection bias. Surgeons from only six hospitals referred patients. The reasons why surgeons did not participate in the study, despite having previously indicated a willingness to participate and despite regular reminders, have remained unclear.

Selection bias has probably not occurred for upper-limb amputees. Of the 225 patients referred, 14 patients were scheduled for or had undergone an upper-limb amputation (through wrist or more proximal), of whom 10 patients had experienced a trauma or CRPS I. This result means an incidence of 0.2/100,000 in the northern Netherlands. Our rate corresponds with the incidence rate of traumatic upper-limb amputations in Sweden, Norway, and the United States, where rates of 0.1, 0.1, and 0.4/100,000 inhabitants, respectively, have been reported [32–34]. In the northern Netherlands, patients with an upper-limb amputation are mainly treated at UMCG. We recommend that future research more clearly report inclusion and exclusion criteria and referral rates.

CONCLUSIONS

In this article, we have given survival rates in a prospective study on patients scheduled for a limb amputation. Our study sample of patients is biased by selection and death. Participants were generally healthier than nonparticipants.
